The importance of evidence for every branch of medicine in teaching in order to orient the practitioners among the great amount of most actual scientific information’s, and to support clinical decisions, is well established in health care, including dentistry.

The practice of evidence-based medicine is a process of lifelong, self-directed, problem-based learning which leads to the need for clinically important information about diagnosis, prognosis, therapy and other clinical and health care issues. Nowadays the practice of dentistry is becoming more complex and challenging because of the continually changing in dental materials and equipments, an increasingly litigious society, an increase in the emphasis of continuing professional development, the information explosion and the consumer movement associated with advances on the Internet.

The need for reliable information and the electronic revolution have come together to allow the “paradigm shift” towards evidence-based health care. Recent years have seen an increase in the importance of evidence-based dentistry, aiming to reduce to the maximum the gap between clinical research and real world dental practice.

Aim of evidence-based practice is the systematic literature review, which synthesizes the best evidences and provides the basis for clinical practice guidelines. These practice guidelines give a brief review of what evidence-based dentistry is and how to use it.

Key words: dentistry; evidence-based medicine; dental care/standards

Evidence-Based Dentistry

“What are we to do when the irresistible force of the need to offer clinical advice meets with the immovable object of flawed evidence? All we can do is our best: give the advice, but alert the advisees to the flaws in the evidence on which it is based”.

The ancestor of this set of pages was created by Dave Sackett and colleagues [1] who generated “levels of evidence” for ranking the validity of evidence about the value of preventive manoeuvres, and then tied them as "grades of recommendations".

Evidence-based practice has been defined as the practice of dentistry that integrates the best available evidences with clinical experience and what a patient prefer in making clinical decisions.

To do it successfully, certain skills need to be obliviously acquired, being the intention of evidence-based dentistry the providing better information for the clinician, improved treatment for the patient, and consequently an increased standing of the profession [2].

The use of evidence-based dentistry may help in the reducing the variations of patient care and outcomes that appears to be associated with four factors: 1. the quality of science underlying clinical care, 2. the quality in making clinical decisions, 3. the variations of the level of clinical skill, 4. the large and increasing volume of literature [3].

Evidence-based dentistry has two main goals: best evidence/research, and the transfer of this in practical use. This involves four basic phases: Asking evidence-based questions (framing an answerable question from a clinical problem); Searching for the best evidence; Reviewing and critically appraising the evidence; Applying this information in a way to help the clinical practice [1,4].

Carr and McGivney [5] have suggested an additional phase that is the evaluation of performance of the techniques, procedures or materials.

In such way it’s possible to obtain advantages in structuring the way to consider clinical problems. This way to approach the clinical decisions becomes increasingly important as in the last 50 years many new materials, drugs, interventions and products have appeared together with new clinical techniques and methods to use these materials. This raises the following questions: how is the average practitioner expected to remain currently updated with these developments, materials and products work as claimed, and which claims will result in improvements for both patient and dentist?

Unfortunately, many questions exist in the obtaining evidence; first of all, it is generally accepted that good clinical researches helpful to obtain evidence...
[6] are above all the prospective randomised controlled trials which are very slow to carry out; besides, another adjunctive problem is the limited space available in journals which makes the time for publication often very long.

In addition, few clinical situations in dentistry are life-threatening, so the impetus to perform rigorous clinical research to compare efficacy of dental therapies may not seem as important as in some other medical therapies [7]. To overcome this, many companies publish pseudo-scientific papers in order to provide some not specific form of evidence only to support their products.

Besides, nowadays also patients ask more frequently several options of treatment [8] because they are generally informed by notice available by internet world. [9,10] and also society has become more litigious [11].

The use of evidence-based dentistry provides a solution to these problems for the dentist. The use of an evidence-based approach can surely help clinicians who want to stay abreast of changes in their areas of health care by assisting them with the selection of relevant articles, and will aid them to efficiently extract and apply the information. [12] Computerised medical databases, such as Medline, Pub Med and The Cochrane Collaboration, have made easier both the distribution and the access to information. [13] These can be found here at the NZDA website.

Today, other strategies available to help the dentist keep abreast with the current information are: [12] Professional journals, many also available on-line; Web-based continuing education programs; Books, audio and video tapes (which often not suggest the most recent information and may suffer from the personal point of view of the author(s); Professional and university continuing education meetings which should give the possibility to interact with the author of a new evidence; Study clubs composed by colleagues.

It is generally accepted that systematic reviews and randomised controlled trials represent the best levels of evidence, whereas case reports and expert opinions are the lowest; with regard to diagnosis, prognosis or causation, cohort studies or case control studies are surely more appropriate, remaining clearly defined in any of these study inclusion and exclusion criteria adopted [14,15]

Nowadays, the majority of today's clinical practice is based on the last three types of study. However, these kinds of study meet the criteria to be considered as evidence-based studies? The questions are: how was the study carried out?; was there an independent, blind comparison with a control?; was allocation of patients to study groups random?; how do the aims and study design contribute to the understanding of a clinical condition or decision?; were the methods for performing the test described in sufficient detail to permit replication?; are the results likely to be valid?; what are the results of the study, and will they help provide better patient treatment?; were both statistical and clinical significance considered?; how does the subject population of the study compare with the patients that make up clinical practice?; are the findings applicable, relevant and feasible in clinical practice?; what are the risks and will the patients be better off? [1,16]

Finally, it should be consider whether the treatment or outcome has some relevance to clinical practice in order to give some benefit to the society.

In the evidence based medicine process, several steps should be performed starting from a clinical problem arising out of the care of patient which creates a well built clinical question; subsequently, appropriate resources should be select and the search conduct in order to appraise the evidence for its validity and applicability in the clinical practice integrating the new evidence with clinical expertise and patient preferences; the last step of this process should be a self-evaluation of the performance with the patient.

With a strict regard to dentistry, it should be underlined that several that many aspects have been introduced without randomised controlled trials, and dental implants are a good example; in fact, many study on implantology are based on a large number of clinical cases and prolonged follow-up but nonetheless uncontrolled. [17] The main reason is that such studies are expensive to conduct, difficult to blind, and often require limited inclusion criteria, or are ethically impossible to undertake. [18] Only by using a hierarchical analysis of the literature, clinicians can make decisions based on the best available evidence.

Evidence-based dentistry is the use of current best evidence in making decisions about the care of individual patients. Carrying out evidence-based dentistry requires that the practitioner question and think about what they are doing, particularly in this era of expectation that dentists will keep abreast of new techniques and developments. Information needs to be assessed, and its validity determined. To properly practice evidence-based dentistry means that time must be spent searching and assessing the literature, and information from any source should be questioned. By formulating a clinical question, carrying out an efficient literature search, evaluating the literature, and when appropriate, applying it to patient care, dentists can meet the challenges of continuing to provide quality care in a rapidly changing environment. Additional benefits are that it makes it easier to justify treatment decisions, especially when there is a complaint or a dento-legal issue.

Conflict of interest

The authors have declared that no conflict of interest exists.

Good reference standards are independent of the test, and applied blindly or objectively to applied to all patients. Poor reference standards are haphazardly applied, but still independent of the test. Use of a non-independent reference standard (where the ‘test’ is included in the ‘reference’, or where the ‘testing’ affects the ‘reference’) implies a level 4 study.

Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and more expensive, or worse and the equally or more expensive.

Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and in the ‘reference’, or where the ‘testing’ affects the ‘reference’) implies a level 4 study.

Clinical Decision Rule. (These are algorithms or scoring systems which lead to a prognostic estimation or a diagnostic category.)

An “Absolute SpPin” is a diagnostic finding whose Specificity is so high that a Positive result rules-in the diagnosis. An “Absolute SnNout” is a diagnostic finding whose Sensitivity is so high that a Negative result rules-out the diagnosis.

Good, better, bad and worse refer to the comparisons between treatments in terms of their clinical risks and benefits.

Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and the equally or more expensive.

Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using a regression analysis) to find which factors are ‘significant’.

By poor quality prognostic cohort study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both exposed and non-exposed individuals and/or failed to identify or appropriately control known confounders and/or failed to carry out a sufficiently long and complete follow-up of patients. By poor quality case-control study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both cases and controls and/or failed to identify or appropriately control known confounders.

Split-sample validation is achieved by collecting all the information in a single tranche, then artificially dividing this into “derivation” and ‘validation’ samples.

An ‘Absolute SpPin’ is a diagnostic finding whose Specificity is so high that a Positive result rules-in the diagnosis. An “Absolute SnNout” is a diagnostic finding whose Sensitivity is so high that a Negative result rules-out the diagnosis.

Good, better, bad and worse refer to the comparisons between treatments in terms of their clinical risks and benefits.

Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and the equally or more expensive.

Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using a regression analysis) to find which factors are ‘significant’.

By poor quality prognostic cohort study we mean one in which sampling was biased in favour of patients who already had the target outcome, or the measurement of outcomes was accomplished in <80% of study patients, or outcomes were determined in an unblinded, non-objective way, or there was no correction for confounding factors.

Good follow-up in a differential diagnosis study is >80%, with adequate time for alternative diagnoses to emerge (eg 1-6 months acute, 1 - 5 years chronic)
