## Abstract

Herein, we purposed to explore whether hypoxia triggers proliferation of cholesteatoma keratinocytes via the PI3K-Akt signaling cascade. Cells were inoculated with different concentration of CoCl<sub>2</sub>. The proliferation and cellular HIF-1 $\alpha$ , p-PDK1 and p-Akt expression levels of cholesteatoma keratinocytes were assessed *in vitro*. Hypoxia escalated cell proliferation via upregulating p-PDK1 and p-Akt expressions. Specific inhibitor of the PI3K-Akt signaling cascade, LY294002 markedly inhibited the expression of p-Akt and significantly reduces the hypoxia-induced proliferation of cholesteatoma keratinocytes. Our data provides research evidence confirming that hypoxia participates in the onset and progress of cholesteatoma.

Key words: hypoxia, cholesteatoma, HIF-1 $\alpha$ , cell proliferation, PI3K/ Akt signaling pathway

## Introduction

Middle ear cholesteatoma, a disease that manifests by both the overgrowth of hyper-keratinized squamous epithelium along with its aggressive clinical course with extensive bone destruction potentially resulting in severe complications, such as refractory otorrhea, balance dysfunction, vertigo, and progressive hearing loss [1]. This disease always demands surgical therapy; however, it is reported that the recidivism rate of this disease was in a wide range, from 4 to 61% [2]. Therefore, the long-term eradication of cholesteatoma is still presenting a challenge for experienced otologists. The scientific pathogenesis of cholesteatoma has been investigated, with progress in studies of many factors, as well as receptors of the cholesteatoma keratinocyte[3]; however, the molecular mechanism responsible for the pathogenesis of cholesteatoma remains unknown.

The theory of a combination of invagination and

proliferation which described by Sudhoff and Tos [4], seems to be applicable to elucidate the retraction pocket in cholesteatoma formation. Based on this observation, the tympanic membrane retraction pocket is commonly secondary to the chronic dysfunction of Eustachian tube. The interruption of aeration through the Eustachian tube exposes the middle ear cavity to reducing pressure and reducing oxygenation; causing hypoxia along with hypercapnia of the middle ear mucosa [5].

It is demonstrated that the hypoxic status in the tympanic cavity can lead to eardrum retraction pockets, followed by cholesteatoma formation. Thus, for long hypoxia has believed as one of the primary factors promoting the onset and progress of cholesteatoma [6, 7]. In the hypoxia status, (HIF-1 $\alpha$ ) hypoxia-inducible factor 1 $\alpha$  is activated and subsequently controls the expression of various genes necessary for mounting cellular responses to hypoxia

[8]. Besides, the HIF-1 $\alpha$  transcription factor is distributed ubiquitously, and has been documented to participate in numerous processes constituting cell proliferation, metabolism, angiogenesis, cell transformation and cell senescence [9]. Increased HIF-1 $\alpha$  contents have been documented in cholesteatoma tissues, and recurrent cholesteatomas result in an elevated degree of hypoxia than ears without surgery patients, suggesting that the cholesteatoma has been recognized as a hypoxic tissue and HIF-1 $\alpha$  plays a vital role in the proliferation ability of cholesteatoma epithelium [6]. However, studies on HIF-1 $\alpha$  expression in cholesteatoma and its relationship with the pathological changes such as cholesteatoma keratinocyte proliferation on one hand, and with the intrinsic signaling pathways on the other hand, have not been fully understood.

The serine/threonine kinase Akt also referred to as protein kinase B has a vital role in cell growth, differentiation, as well as survival [10]. The phosphoinositide 3-kinase (PI3K)-dependent signaling cascade activates Akt in response to diverse stimuli consisting of certain cytokines and growth factors [11]. In the hypoxia status, the PI3K-Akt signaling cascade is activated in distinct cells, such as pulmonary arterial smooth muscle, porcine coronary artery endothelial, A549 cells, as well as rat hepatocytes, while other cells; consisting of HEK293T, PC-3, U373, COS-7, and 3T3 cells do not exhibit elevated Akt phosphorylation levels [12, 13]. Previous investigations have demonstrated that the PI3K-Akt-Cyclin D1 signaling cascade is activated in cholesteatoma epithelium and has a critical role in cholesteatoma keratinocytes hyperproliferation [1]. Previous studies revealed that hypoxia increased cell proliferation for cholesteatoma keratinocytes [2]. However, the relationship between the PI3K-Akt signaling cascade and hypoxia-induced proliferation in cholesteatoma keratinocytes remains unclear.

Herein, we explored whether PI3K-Akt signal cascades are activated by hypoxia and, if so, to elucidate their function and signaling cascades in cholesteatoma keratinocytes. Our data illustrated that hypoxia triggered transient activation of the PI3K-Akt survival signaling cascades via a PKC-dependent mechanism. These signals were linked to proliferation of cholesteatoma keratinocytes when exposed to hypoxia.

## Materials and methods

### Materials

LY294002 was supplied by MedChem Express (NJ, United States). All the reagents used herein were of analytical grade.

### Tissue Sample and immunofluorescence

Tissue samples were acquired from 10 study participants (five participants with primary acquired cholesteatoma and five participants with normal external canal skins) for immunofluorescence and Western blot. The Research Ethics Committee of the Eye and ENT Hospital of Fudan University approved the study. Moreover, the study subjects gave written informed consent. After surgery, these cholesteatoma samples were split into two parts for immunohistochemical analyses and cell culture. The immunohistochemical samples were fixed with 4% PFA for 24 hours and then paraffin-embedded. Afterwards, 5-mm slices were employed for immunofluorescence as documented previously. Graded alcohol was employed to deparaffinize and rehydrate the sections, followed by blocking for one hour in 10% normal goat serum. Next, the samples were rinsed, and then inoculated with primary antibodies against HIF-1 $\alpha$  antibody (Cat No GTX628480, Genetex, Cambridge, MA, USA; 1:200), HIF-1 $\alpha$  antibody (Cat No GTX127309, Genetex, Cambridge, MA, USA; 1:200) and Pan-keratin (Cat No 4545, CST, Danvers, MA, USA; 1:200). Thereafter, the samples were inoculated with Alexa 546-conjugated or Alexa 488-conjugated goat anti-rabbit/mouse antibodies for one hour at RT (room temperature). Then, staining of the sections with DAPI was performed. Lastly, Axioskop microscope (Carl Zeiss, Oberkochen, Germany) was employed to image the samples.

### Cell culture and stimuli

A previously documented protocol was employed to isolate and characterize the cholesteatoma keratinocytes [14]. Concisely, cholesteatoma tissues were acquired from study subjects via surgical resection and hand carried to our laboratory. A scissors was used to slice the tissues into small slices. Afterwards, the tissue slices were inoculated with 200 U/ml collagenase IV (Cat No C5138, Sigma Aldrich, St. Louis, MO, USA) overnight at 4°C to dissociate the tissues. Next, HBSS was employed to rinse the tissues twice, followed by spinning at 1,500 rpm for five minutes. The supernatant was discarded and the pellet inoculated with KFSM medium (Cat No 17005042, Invitrogen, Carlsbad, CA, USA) enriched with 500 u/ml streptomycin/penicillin (Cat No 15070063, Invitrogen, Carlsbad, CA, USA), and grown under 5% CO<sub>2</sub> and 37°C conditions. After every three days, we changed the KFSM media along with the antibiotics. The cell cultures of between the 3<sup>rd</sup> and 4<sup>th</sup> passages were used in the assays. In all the assays, unless indicated, 1x10<sup>5</sup> cells/cm<sup>2</sup> were planted in culture

plates and allowed to grow to a confluence of between 70% and 80% for use. Pretreatment with inhibitor, LY294002 as a PI3K inhibitor (Cat No HY-10108, MedChem Express, NJ, United States), was accomplished via the introduction of the inhibitor one hour before induction in the presence or absence of hypoxia. Hypoxic conditions were introduced by treating cells with 50  $\mu$ M to 200  $\mu$ M concentrations of  $\text{CoCl}_2$  in a cell incubation chamber (Don Whitley Scientific Ltd., Shipley, UK) for the specified time.

### EdU staining proliferation assay

The EdU imaging kit (Cat No C10638, Invitrogen, Carlsbad, CA) was employed to assess cell growth after the specified treatments as described by the manufacturer. In brief,  $5 \times 10^3$  Cholesteatoma keratinocytes/well were inoculated in KFSM medium in the Lab-Tech chamber slide (Nalge Nunc International, Cambridge, MA, USA) until they attained a confluence of 70-80%. These cells were subsequently inoculated with LY294002 (10  $\mu$ M) one hour before exposure to indicated oxygen conditions for specified period. After that, the cells were fixed with 4% PFA for 15 minutes, followed by permeabilization for another 15 minutes using 0.3% Triton X-100 dissolved in PBS. Afterwards, we inoculated the cells in a Click mixture (Click reaction buffer, reaction buffer additive,  $\text{CuSO}_4$ , and Alexa Fluor® 555 Azide) for 30 minutes in the dark. The cells were then inoculated with 5  $\mu$ g/mL Hoechst 33342 for 10 minutes for DNA staining. Lastly, a fluorescent microscope was employed to image the cells, and the proportion of EdU-positive cells determined.

### Western blot analysis

After, the specified treatments, ice-chilled PBS was employed to wash the PAFs twice. Afterwards, 0.15 ml cell lysis buffer (Cat No P0013, Beyotime Institute of Biotechnology, China) enriched with protease inhibitor was employed to lyse the cells for 15 minutes. Next, the BCA kit (Cat No, Beyotime Institute of Biotechnology, China) was employed to quantify the proteins. Subsequently, 30  $\mu$ g/lane proteins were fractionated on a 10% SDS-PAGE gels. The fractionated proteins were blotted onto PVDF membranes (300 mA for one hour). The membranes were inoculated with the primary antibodies and incubated at 4°C overnight. Thereafter, the membranes were inoculated with the secondary peroxidase-labelled antibody for one hour. The protein bands were detected via enhanced chemiluminescence and exposure to ECL Hyperfilm (GE Healthcare). NIH Image 1.63 software was employed to quantify the densitometry of bands.

Beta-actin served as the normalization standard. The primary antibodies used included anti-phospho-PDK1 (1:1,000), anti-protein kinase B (AKT) (1:1,000) and anti-phospho-AKT (Ser 473; 1:1,000) (All from Cell Signaling Technology, Danvers, MA, USA). Antibodies against  $\beta$ -actin (1:1,000) and HIF-1  $\alpha$  (1:2,500) were from Genetex, Inc. (Genetex, CA, USA).

### Statistical analyses

The data are given as the mean  $\pm$  standard deviation (SD). Paired Student's t-test was implemented to compare two groups.  $P < 0.05$  signified statistical significance.

## Results

### Immunolocalization of HIF-1 $\alpha$

HIF-1 $\alpha$  expression in cholesteatoma tissue was remarkably upregulated relative to the normal skin according to the results of the immunofluorescence experiments (Fig. 1). In the healthy skin, scanty staining of HIF-1 $\alpha$  was seen (Fig. 1A-C). In cholesteatoma tissue, HIF-1 $\alpha$  was obviously expressed in the cytoplasm of the basal and parabasal cell layers (Fig. 1D-F). Next, we performed a co-stained of intrinsic hypoxia marker HIF-1 $\alpha$  (Fig. 2A-C) and a keratinocyte marker Pan-keratin (Fig. 2D-F) in the cholesteatoma samples, and demonstrated that the staining of HIF-1 $\alpha$  and Pan-keratin was present in cytoplasm. In addition, we observed a co-expression of Pan-keratin and HIF-1 $\alpha$  in the epithelium of cholesteatoma, strongly suggesting that HIF-1 $\alpha$  is upregulated in cholesteatoma keratinocytes.

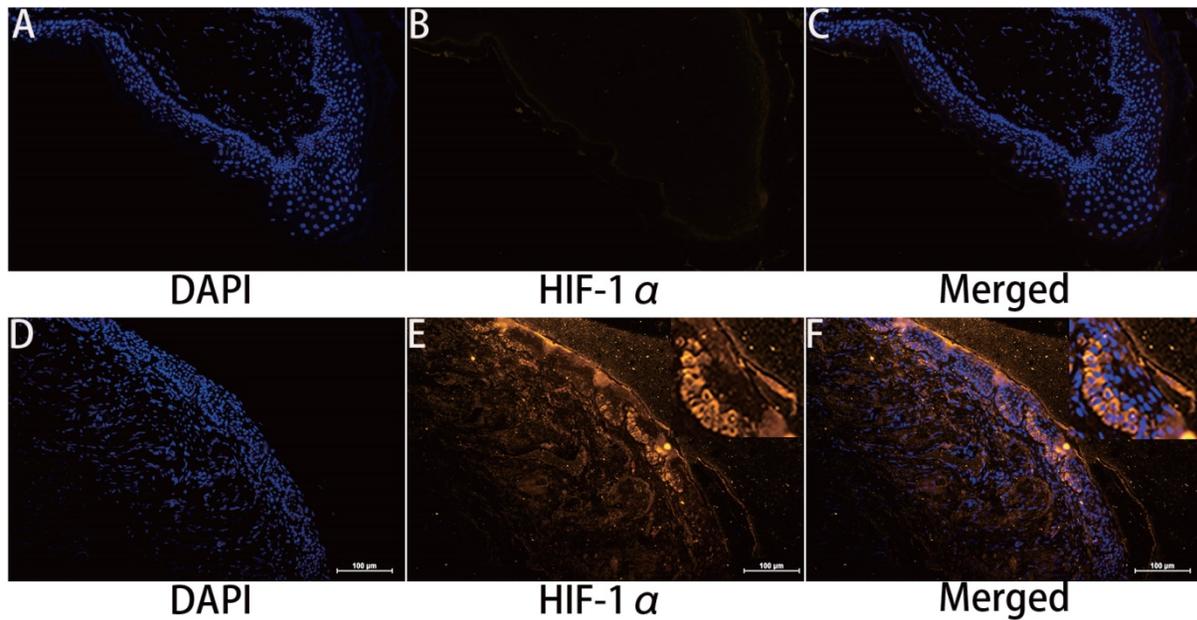

To further confirm the effective expression of HIF-1 $\alpha$ , we performed western blotting analysis. Results showed that the protein expression of HIF-1 $\alpha$  in cholesteatoma tissues was significantly higher than that in the normal skin ( $P < 0.05$ ) (Fig. 2G).

### CoCl<sub>2</sub>-simulated hypoxia upregulates HIF-1 $\alpha$ expression in cholesteatoma keratinocytes

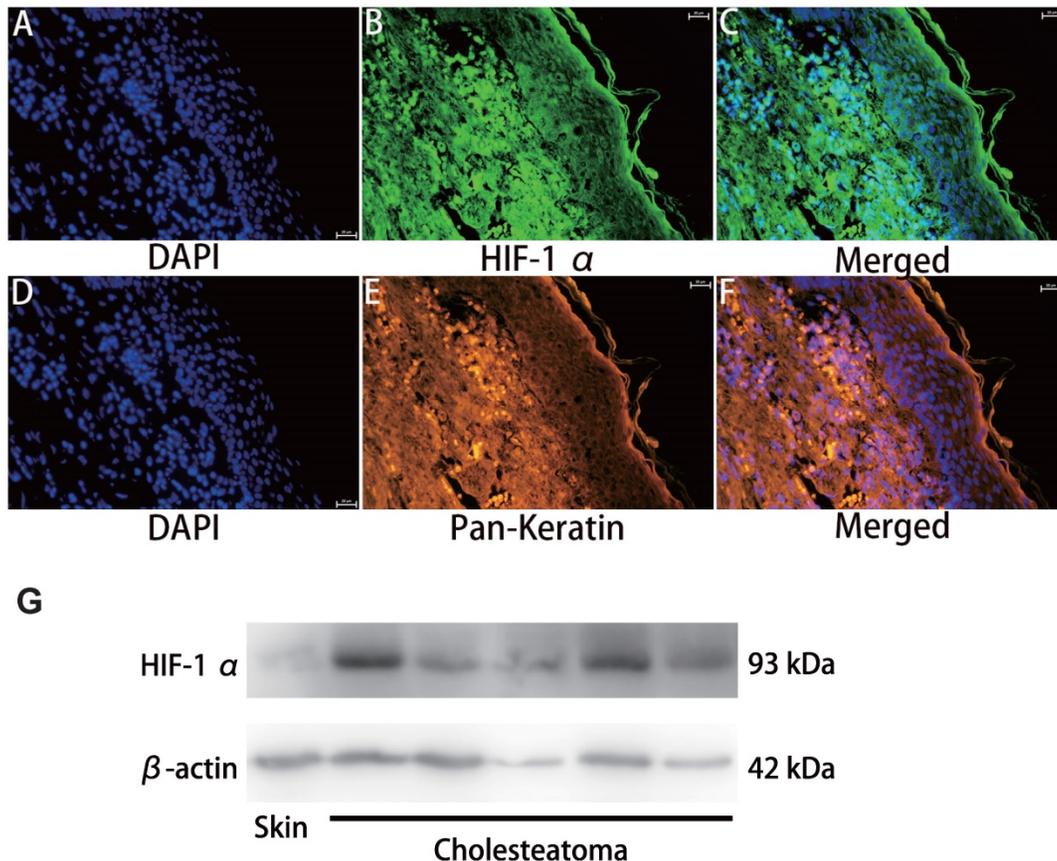

$\text{CoCl}_2$  triggers HIF-1 $\alpha$  protein aggregation in numerous kinds of cells [15]. To explore if  $\text{CoCl}_2$  influenced HIF-1 $\alpha$  expression, cholesteatoma keratinocytes were inoculated with  $\text{CoCl}_2$  for different times and HIF-1 $\alpha$  protein expression was assessed via western blotting. As illustrated in Fig. 3A, the increase in HIF-1 $\alpha$  protein expression in  $\text{CoCl}_2$ -treated cells was observed by fluorescent microscopy. Additionally, the HIF-1 $\alpha$  protein expression increased dose-dependently after  $\text{CoCl}_2$  treatment. Based on these data, the stimulation of HIF-1 $\alpha$  under 200  $\mu$ M  $\text{CoCl}_2$  was optimal. To explore if HIF-1 $\alpha$  expression occurred in a time-dependent approach, the cells were inoculated with 50  $\mu$ M  $\text{CoCl}_2$  for 0, 24, 48 and 72

hours, and HIF-1 $\alpha$  expression was assessed via western blotting. As indicated in Fig. 3B-C, HIF-1 $\alpha$  expression was higher under hypoxia conditions (50  $\mu$ M CoCl<sub>2</sub>), peaked at 24 hours and reduced after 24 hours, implying that internal mechanism repressed

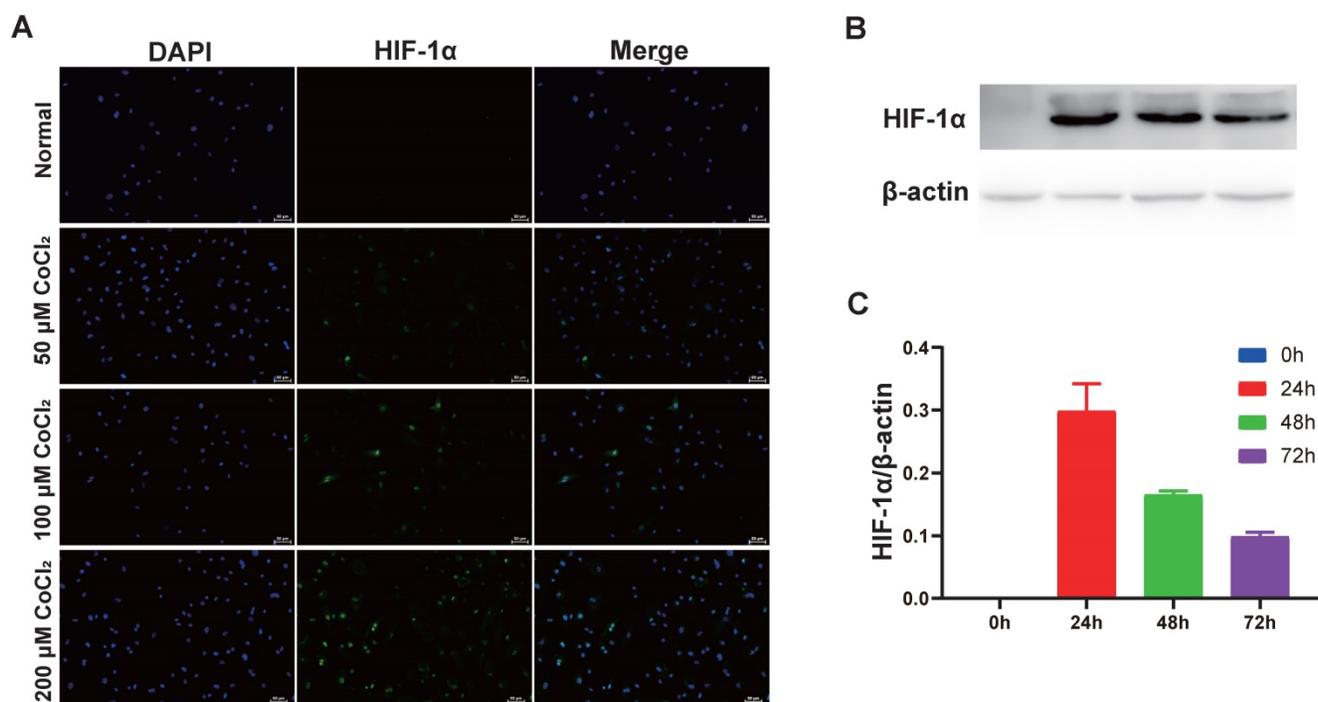

further increase in HIF-1 $\alpha$  expression. Thus, hypoxia induced by CoCl<sub>2</sub> treatment was critical in upregulating HIF-1 $\alpha$  protein expression in cholesteatoma keratinocytes.

**Figure 1.** Immunohistochemical staining for hypoxia inducible factor 1 $\alpha$ . HIF-1  $\alpha$  is scantily expressed in external auditory canal skin (A–C). HIF-1  $\alpha$  is expressed in the cytoplasm of cholesteatoma keratinocytes in the parabasal, as well as basal layers of cholesteatoma epithelium (D–F). The highest staining intensity is evident in basal layer keratinocytes (magnification,  $\times$ 200).

**Figure 2.** Double immunofluorescence staining and western blotting analyses of hypoxia inducible factor 1 $\alpha$  and Pan-keratin in human cholesteatoma tissues. HIF-1 $\alpha$  (A–C) and Pan-keratin (D–F) was present in the cytoplasm of cholesteatoma keratinocytes in the cholesteatoma epithelium (magnification,  $\times$ 400). (G) Western blotting images of HIF-1 $\alpha$ .

**Figure 3.** Hypoxia increases HIF-1 $\alpha$  expression in cholesteatoma keratinocytes. (A) Cells were inoculated with 50  $\mu$ M, 100  $\mu$ M and 200  $\mu$ M CoCl<sub>2</sub> for 24 h and the HIF-1 $\alpha$  protein was stained and observed by fluorescent microscopy (magnification, x200). (B) Cholesteatoma keratinocytes were inoculated with 50  $\mu$ M CoCl<sub>2</sub> for 0, 24, 48, 72 h and HIF-1 $\alpha$  expression was assayed by western blotting. (C) Results represent three independent experiments.  $\beta$ -actin served as the loading control. Data are given as mean  $\pm$  standard error of the mean.

### CoCl<sub>2</sub>-simulated hypoxia enhances the proliferation of cholesteatoma keratinocytes.

To explore the function of hypoxia on cell proliferation, the cholesteatoma keratinocytes were inoculated with varied concentrations of CoCl<sub>2</sub> for 1-48 h and the proliferated cell number was quantified using an EdU assay. As indicated in Fig. 4A and 4D, hypoxia enhanced cell proliferation in a concentration-dependent approach after CoCl<sub>2</sub> treatment for 24 h. In addition, the promotion of proliferation under severe levels of hypoxia (200  $\mu$ M CoCl<sub>2</sub>) was more marked. The number of EdU-positive cell increased in hypoxia, peaked at 24 h and decreased after 24 h, suggesting prolonged hypoxia inhibited cell proliferation (Fig. 4E). In conclusion, hypoxia, to some extent, enhances the proliferation of cholesteatoma keratinocytes.

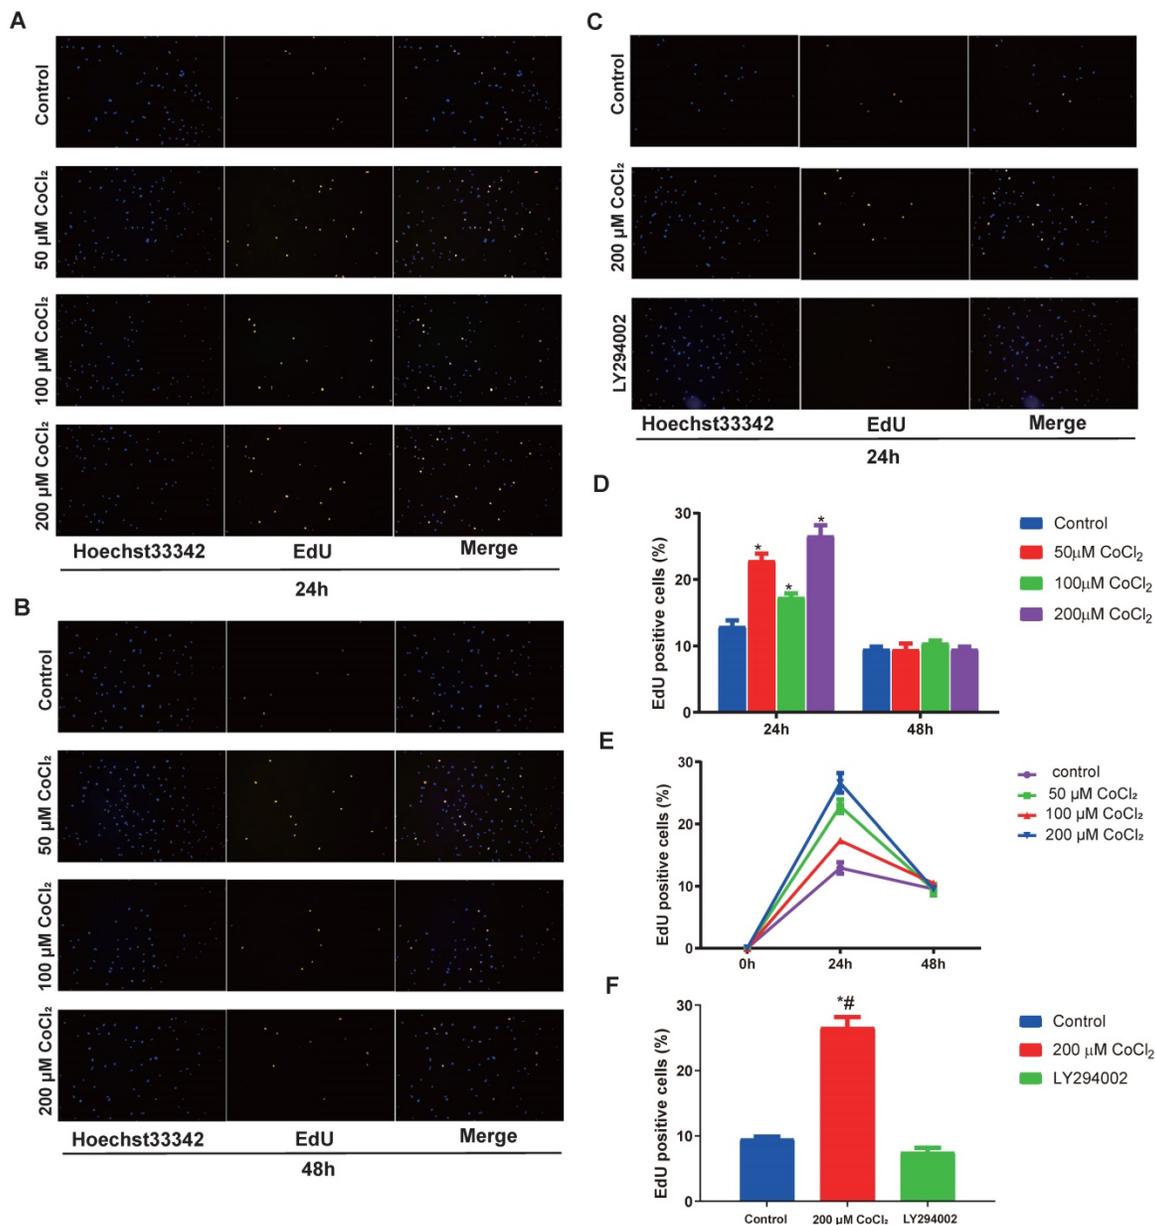

### CoCl<sub>2</sub>-simulated hypoxia promotes the proliferation of cholesteatoma keratinocytes via the phosphoinositide 3-kinase (PI3K)/Akt pathways.

Previous investigations have documented that the PI3K-Akt cascades play an important role in modulating the proliferation of cholesteatoma. Herein, we explored whether this signaling cascade was involved in modulating the proliferation of cholesteatoma keratinocytes under hypoxic status.

The cholesteatoma keratinocytes were inoculated with varied CoCl<sub>2</sub> concentrations and the contents of PDK1, Akt and p-Akt were assessed with western blotting. Based on the western blot analysis results (Fig. 5A), hypoxia remarkably elevated the activation of PDK1 and p-Akt. To explore if the hypoxia-triggered activation of Akt particularly modulated the cell proliferation of cholesteatoma keratinocytes, the PI3K-Akt cascade was repressed by LY294002, a suppressor of PI3K. The LY294002 (10  $\mu$ M) remarkably reduced the activation of p-Akt (Fig. 5B) and inhibited the proliferation of cholesteatoma keratinocytes (Fig. 4C, 4F). These data illustrated that hypoxia-triggered proliferation of cholesteatoma keratinocytes is dependent on the PI3K-Akt pathways.

### Discussion

In this study, we have provided evidence that HIF-1 $\alpha$ , act as hypoxic-associated molecule is highly expressed in human cholesteatoma tissues. In line with previous works [6], our result confirm that cholesteatoma is a hypoxic tissue. Evidently increased staining was reported in the keratinocytes located in the basal layer of the cholesteatoma epithelium. This result suggests that hypoxia participates in the control of proliferation of cholesteatoma epithelial cells and act as a central mediator in the formation of the hyperplastic epithelium.

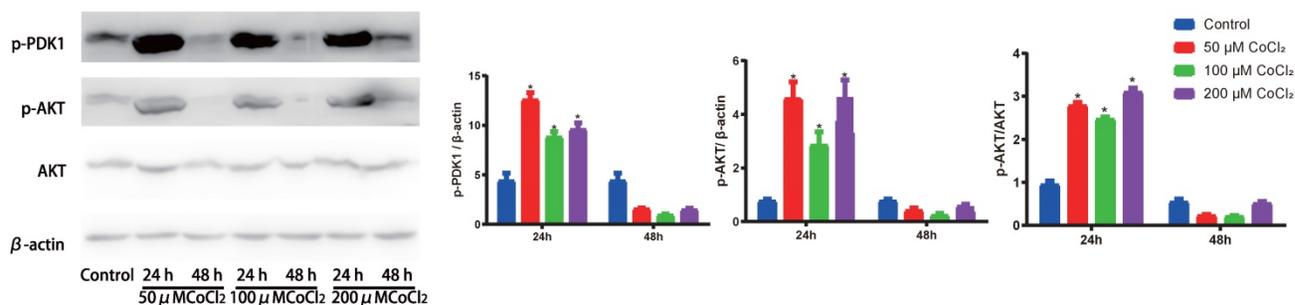

**Figure 4.** Hypoxia-induces the proliferation of cholesteatoma keratinocytes *in vitro*. (A-C) The proliferation of cholesteatoma keratinocytes was explored using EdU assay after treatment as specified for 24 and 48 h (n=5). (D) Hypoxia enhanced cell proliferation in a concentration-dependent approach after CoCl<sub>2</sub> treatment for 24 h. The optimal concentration of CoCl<sub>2</sub> is 200 μM (n=5). (E) Hypoxia enhanced cell proliferation in a time-dependent approach after CoCl<sub>2</sub> treatment, peaked at 24 h and decreased after 24 h (n=5). (F) The proliferation of cholesteatoma keratinocytes was inhibited followed treatment with LY294002. \*P<0.05.

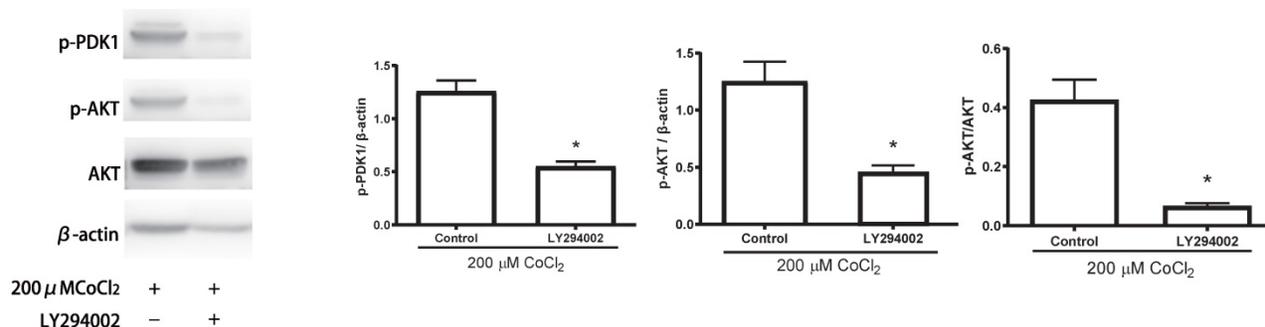

As mentioned above, cholesteatoma is a hypoxic tissue; however, the impact of hypoxia on cholesteatoma keratinocytes has not been thoroughly investigated. In this study, we inquired the effects of CoCl<sub>2</sub>-simulated hypoxia on the cholesteatoma keratinocytes. Because CoCl<sub>2</sub> strongly stabilizes HIF-1/2α under normoxia, CoCl<sub>2</sub>-induced chemical hypoxia becomes one of most commonly used models to simulate hypoxia [16]. Hypoxia can variably affect cell growth via diverse mechanisms in different cell types. Hypoxia inducible factors (HIFs) are understood to be the master regulators of the cellular response to hypoxia [8]. The HIF-1/2 are dimer consisting of HIF-1/2α protein subunit and the beta

subunit aryl hydrocarbon receptor nuclear translocator (ARNT) or HIF-β protein subunit [8]. During normoxia, PHD enzymes can hydroxylate HIF-1/2α with help of oxygen, iron (Fe<sup>2+</sup>) and α-ketoglutarate, followed by polyubiquitination by the VHL complex and subsequent proteasomal degradation [8]. It is well known that the mechanism by which CoCl<sub>2</sub> stabilizes HIF-1/2α is the displacement of Fe<sup>2+</sup> by Co<sup>2+</sup> in PHDs active site provoking inhibition of these key enzymes [16]. Thus, the CoCl<sub>2</sub>-induced hypoxia model is reliable for us to analyze the effect of hypoxia on cholesteatoma keratinocytes.

A

B

**Figure 5.** Hypoxia activates the PI3K-Akt signaling cascade in cholesteatoma keratinocytes. (A) Western blotting assay of specified proteins in cholesteatoma keratinocytes after inoculation with 50 μM, 100 μM and 200 μM CoCl<sub>2</sub> for 24 h and 48 h. (B) Western blotting assay of the specified proteins in cholesteatoma keratinocytes after inoculation with LY294002 and hypoxia as specified for 24 h. \*P<0.05.

Herein, we found that culture of cholesteatoma keratinocytes isolated from cholesteatoma tissues under hypoxic conditions caused a concentration-dependent promotion of keratinocyte proliferation and increased HIF-1α expression under hypoxia conditions. In addition, we found that cholesteatoma keratinocytes exposed to hypoxia for 24 hours were still able to grow, however at a slower rate relative to cells grown in normoxia. This lower cell count reported under conditions of prolonged hypoxia does not appear to be due to apoptosis, because cell showed no apoptotic morphological changes. Thus, hypoxia can enhance proliferation and prolonged hypoxia can induce a state of quiescence in cholesteatoma keratinocytes.

CoCl<sub>2</sub>-simulated hypoxia activates HIF-1/2α, which transcriptionally regulate numerous genes that play important roles in angiogenesis, metabolism, erythropoiesis, cell fate, survival, invasion and metastasis [17]. It is reported that inducing the cell proliferation of breast cancer [18] and osteosarcoma cells [19] under CoCl<sub>2</sub>-simulated hypoxia is HIF-1 α dependent. However, it has been also demonstrated that synovial mesenchymal stem cells (SMSCs) [20] merely grow better under hypoxia along with upregulation of HIF-1 α. Moreover, other cells of (synovial, human renal carcinoma cell line as well as

human cervical carcinoma cells) show depressed growth [21, 22]. Therefore, the proliferation effect of HIF-1 α during exposure to hypoxia is cell type- and organ-specific.

Recently, HIF-2α has also been shown to be capable of regulating the transcription of genes that are regulated in hypoxia [23]. HIF-2α has a more limited tissue distribution of expression, such as endothelium, kidney, heart, lungs, and small intestine [24]. It has also been suggested to play an important role in cancer responses to hypoxia through the promotion of cell proliferation and migration [23]. Interestingly, HIF-2 α promoted hypoxic cell proliferation of von Hippel-Lindau (VHL)-deficient carcinoma cell in a c-Myc-dependent or mTORC1 activation fashion, while HIF-1 α inhibited their growth [24, 25]. In addition, other research showed that *in vivo* exposure to hypoxia led to a remarkable proliferation of bronchial epithelium [26] and carotid body [27]. Thus, it will be interesting to further look into the interplay between HIF-2 α and hypoxia-induced cell proliferation of cholesteatoma keratinocytes.

To explore the potential mechanisms responsible for this enhanced proliferation, we focused on the PI3K-Akt signaling cascade. PI3K might be activated by growth factors, as well as hormones, and in turn

mobilizes PDK1 along with PDK2 to the cell membrane, and then PDK1/PDK2 cooperate to activate Akt completely [3]. Akt enhances cell survival via repressing apoptosis, and is also linked to the modulation of the cell cycle. Previous investigations have documented that the PI3K-Akt signaling cascade serves a crucial role in the hyperproliferation of cholesteatoma epithelial [3]. Herein, we speculated the PI3K-Akt signaling cascade participates in the hypoxia-mediated proliferation of cholesteatoma keratinocytes, and could be associated with hypoxia-induced initiation and formation of cholesteatoma.

The *in vitro* study illustrated that the PI3K-Akt signaling cascade in cholesteatoma keratinocytes was remarkably activated by hypoxia. Herein, cholesteatoma keratinocytes revealed distinct potential to proliferate in response to hypoxia without exogenous growth factors. It was subsequently considered that the PI3K-Akt signaling cascade participates in hypoxia-triggered proliferation behaviors of cholesteatoma keratinocytes. Specific inhibitor of the PI3K-Akt signaling cascade, LY294002 was employed to assess this, and it was illustrated that the hypoxia-triggered proliferation was notably inhibited under the inhibitor treatment. This enhanced the evidence that the PI3K-Akt signaling cascade was critical for the hypoxia-induced proliferation in cholesteatoma keratinocytes.

## Conclusions

The present study illustrated that hypoxia activates HIF-1 $\alpha$  and enhances cell proliferation through the PI3K-Akt pathways in cholesteatoma keratinocytes. These findings suggested that the tissue hypoxia encountered in pathophysiological conditions could contribute to the hypoxia-linked progression of the retraction pocket by promoting concurrent cellular growth. In addition, these data may be helpful for supporting the view that hypoxia plays a vital role in the formation of acquired cholesteatoma.
